Abstract

In the previous decade, dozens of studies involving thousands of children across several research disciplines have made use of a combined daylong audio-recorder and automated algorithmic analysis called the LENATM system, which aims to assess children’s language environment. While the system’s prevalence in the language acquisition domain is steadily growing, there are only scattered validation efforts, on only some of its key characteristics. Here, we assess the LENATM system’s accuracy across all of its key measures: speaker classification, adult word counts (AWC), child vocalization counts (CVC), and conversational turn counts (CTC). Our assessment is based on manual annotation of clips that have been randomly or periodically sampled out of daylong recordings, collected from (a) populations similar to LENATM’s original training data (North American English-learning children aged 3-36 months), (b) children learning another dialect of English (UK), and (c) slightly older children growing up in a different linguistic and socio-cultural setting (Tsimane’ learners in rural Bolivia). We find reasonably high accuracy in some measures (AWC, CTC), with more problematic levels of performance in others (CTC, precision and recall of male adults and other children). We find little difference in accuracy as a function of child age, dialect, or socio-cultural setting. Whether LENATM results are accurate enough for a given research, educational, or clinical application depends largely on the specifics at hand. We therefore conclude with a set of recommendations to help researchers make this determination for their goals.

A thorough evaluation of the Language Environment Analysis (LENATM) system

While nearly all humans eventually become competent users of their language(s), documenting the experiential context of early acquisition is crucial for both theoretical and applied reasons. Regarding theory, there are many open questions about what kinds of experiences and interactions are necessary, sufficient, or optimal for supporting language development. Moreover, the ability to accurately and quickly assess an infant’s state of development at a given point in time is of central importance for clinical purposes, both for children with known risks of language delays and disorders, and those who might not be identified based on risk factors. Reliable assessments are also crucial for measuring intervention efficacy.

One approach that has been making its way into the mainstream literature across basic and applied research on language and cognition relies on day-long recordings gathered with a LENATM audiorecorder (J. Gilkerson et al., 2017; e.g., Greenwood, Thiemann-Bourque, Walker, Buzhardt, & Gilkerson, 2011; Oller et al., 2010), and further analyzed using LENATM’s automated, closed-source algorithms. As we summarize below, this approach has many advantages, which may explain its expanding popularity. While dozens of papers over the past decade have used LENATM’s automated output, only a handful include validity estimates (d’Apice, Latham, & Stumm, 2019; e.g., Weisleder & Fernald, 2013; Zimmerman et al., 2009), even fewer where validity estimation was the primary focus of the paper (F. Bulgarelli & Bergelson, in press; e.g., Canault, Le Normand, Foudil, Loundon, & Thai-Van, 2016; Ganek & Eriks-Brophy, 2018; Lehet, Arjmandi, Dilley, Roy, & Houston, 2018). As a result, few studies report sufficient details about validation accuracy for one or more metrics, limiting the interpretability of the results of a meta-analytic assessment (as attempted in A. Cristia, Bulgarelli, & Bergelson, 2019).

The work undertaken thus far also has some limitations, which are described further in the “Previous Validation” section below, and mentioned briefly next. First, many validations or evaluations of LENATM omit analysis of the less-directly “relevant” categories of input

like noise, silence, or overlap. Second, many LENATM evaluations rely on LENATM’s own output as a starting point to either select portions of the file for manual annotation, or use its segmentation into talker turns or vocalizations as the unit of analysis rather than segmenting the audio from scratch. Both decisions can lead to inflated accuracy estimates. Here we endeavor to conduct an evaluation that is fully independent of the LENATM algorithms’ automated assessment, permitting a systematic, extensive, and independent evaluation of its key metrics.

In a nutshell, this paper reports on the performance of LENATM algorithms when compared to human annotations carried out in clips extracted from daylong audiorecordings gathered from (a) a sample of children similar to the LENATM training set (i.e. infants and toddlers, growing up in North American English-speaking homes, and aged 3-36 months), (b) a group of similarly aged children learning a different dialect (UK English); and (c) slightly older children learning a different language in a very different sociocultural setting (Tsimane’-learning children in rural Bolivia).

Brief introduction to LENATM products. The LENATM system consists of a hardware component (a lightweight, sturdy, and easy-to-use recording device worn by a child in specialized clothing) and a suite of proprietary computer programs designed to provide automated quantitative analyses of the auditory environment and the child’s own vocalizations. The latter was developed over an extensive corpus of full day audio recordings gathered using their patented recording hardware (Xu, Yapanel, & Gray, 2009). The original dataset included over 65,000 hours of recording across 329 American English-speaking families chosen for diversity in child age (1-42 months) and socio-economic status (J. Gilkerson & Richards, 2008). Half-hour selections from 309 recordings were transcribed and annotated for the purpose of developing the algorithm, and an additional 60 minutes from each of 70 recordings were transcribed and annotated for testing the result (Gilkerson, Coulter, & Richards, 2008).

The resulting LENATM software takes as input a new audio recording and processes it

incrementally in short windows, extracting a variety of acoustic features which are used to classify the audio stream into segments of at least 600 ms in length (or longer for some of the categories) using a Minimum Duration Gaussian Mixture Model (MDGMM; Xu et al., 2009). Silence may be included to “pad” segments to this minimum duration. The segments are classified according to a set of broad speaker and non-speaker classes. The speaker classes are: Male Adult, Female Adult, “Key” Child (i.e. the one wearing the recorder) and Other Child. The non-speaker classes are: Noise, Television (including any electronics), Overlap (speech overlapped with other speech or nonspeech sounds), and Silence (SIL). With the exception of Silence, these classifications are then passed through a further likelihood test between the original classification for a given segment and the Silence class, the result of which determines whether they are “Near” (high probability of being that class) or “Far” (low probability, they may be silence instead). Given the large number of acronyms and labels of various kinds, we provide a listing of relevant LENATM abbreviations on Table 1; in what follows, we highlight the specific labels that we evaluate in the present work in bold.

After this broad speaker classification step, Female or Male Adult “Near” segments (FAN and MAN) are further processed using an adaptation of the Sphinx Phone Decoder (Lamere et al., 2003) in order to form an automated estimate of the number of words in each segment (Adult Word Count, or **AWC**). Key Child (CHN) segments are further processed to sub-classify regions in them into vegetative noises, crying, and speech-like vocalizations. LENATM provides the count (child vocalization count, or CVC) and duration of the latter, speech-like sub-segments. A further metric, Conversational Turn Counts (CTC), reflects the number of alternations between an adult and the key child (or vice versa), bounded by maximally 5 s of non-speech.

Previous validation work. A recent systematic review (A. Cristia et al., 2019) found 23 papers, containing 28 studies, reporting on the accuracy of LENATM’s labels and derived metrics (AWC, CVC, CTC). They conclude that there are ‘reasonably good results [overall]: over 61% for recall and precision based on 11-12 non-independent studies;

Table 1

A partial listing of common LENA abbreviations and their meanings.

Abbreviations	Meanings
FAN, MAN, CHN, CXN	Basic “meaningful speech” (near and clear speech) categories used by LENA for further processing: Female Adult Near, Male Adult Near, Key Child Near and Other Child Near categories respectively.
NON, TVN, OLN, SIL	Basic non-speech categories: Noise Near, Television Near, Overlap Near, Silence.
FAF, MAF, etc.	“Far” (low probability) versions of each category.
Key child	Child wearing recorder
AWC	Adult Word Count (estimated within FAN and MAN vocalizations)
AVA	A measure of vocal maturity processed over VOC
CVC	Child Vocalization Count (estimated for non-cry, non-vegetative portions of CHN)
CTC	Conversational Turn Count (estimated over FAN/MAN and CHN turns)

correlations for AWC mean $r=.79$, on $n=11$, with a mean RER [i.e., Relative Error Rate]=10% on $n=11$; CVC mean $r=.76$, $n=5$, with a mean RER=1% on $n=5$. The exception to this general trend towards good performance was CTC, with a mean $r=.31$, $n=5$, RER=-64% on $n=2$.’ The systematic review also identified several limitations of the body of previous validation work. First, for the majority of included studies, the validity report was not fully evaluated by peer review. Even if the study may have appeared in a journal with a peer reviewed process, the validation in itself was often a secondary goal to support a different research objective, and therefore often lacked methodological details or even full results. For instance, Seidl et al. (2018) report on validation of LENATM labels among

children at familial risk for autism in a one-paragraph appendix to the paper, which only mentions confusions between female adult and child. It is not clear whether confusions between key child and any other category (other child, male adult, silence, etc.) were ignored rather than counted as an error. While this approach may be reasonable for a given study’s research goals, it has the undesirable side effect of creating the impression that LENATM metrics are widely validated, while in fact validation methods may not have been reported or evaluated in detail. Second, previous studies typically did not take silence, noise, or overlap into account in the reported confusion matrices or other accuracy measures, particularly within segments. That is, if a LENATM segment labeled ‘key child’ contained one second of silence and two seconds of speech by the key child, the full three second clip may be tagged as ‘correct’ though it was only 67% correct, leading to an overestimation of the accuracy of the “key child” label.

Third, a majority of previous validation studies used the LENATM output itself to select the sections that would be annotated for validation (in A. Cristia et al., 2019, this held for 14/25 studies that specified the method of selection). For instance, clips may have been selected for manual annotation on the basis of high AWC and/or CTC according to the algorithm. This unfortunately leads to biased sampling: Since LENATM only counts words within FAN and MAN segments and conversational turns involving FAN/MAN alternations with CHN in close proximity, high AWC or CTC can only occur in sections of the recording that are “clean” enough for the algorithm to parse; otherwise, most of the section would have been classified as overlap (OLN), which does not count towards AWC or CTC. This would tend to bias these reports toward a higher level of accuracy than would be obtained across the full recording.

Forth, previous validation work has typically focused on a single corpus, participant population, age range, and language. As a result, although considerable variation in performance has sometimes been reported (Canault et al., 2016; e.g., J. Gilkerson et al., 2016) it is difficult to assess whether a numerical difference in accuracy found is significant,

and if so, whether this is due to a difference in the way the corpus was constituted and annotated, rather than on how LENATM fares with that population, age range, and language.

The present work. We sought to assess the validity of LENATM’s metrics through an approach that complements the preceding literature. Specifically, we report an evaluation of all speech labels and some non-speech labels of LENATM, namely: silence (SIL), overlap near (OLN), overlap far (OLF); as well as LENATM’s key derived metrics: adult word count (AWC), conversational turn count (CTC), and child vocalization count (CVC). We aim to address several of the limitations found in the body of previous work.

First, to maximally avoid potential bias in our annotations, we used random or periodic sampling (detailed below) to choose which sections of daylong recordings to annotate, and did not give annotators access to the LENATM output. Second, to allow assessment of the accuracy of the segmentation itself as well as categorical labeling, evaluation is done at the level of 10 ms frames rather than segments. This allows us to capture a much finer-grained representation of the auditory environment (i.e., if LENATM classified a 2 s audio segment as FAN, but .8 s of this was actually non-speech noise or a different talker, LENATM would be credited only for the proportion that was correct).

Third, to gain traction on generalizability, rather than focusing on a single sample that either mirrors or diverges from LENATM’s original population, we included five corpora. Three corpora sampled from the same population, language, dialect, and age group the LENATM softawer was developed with. A fourth corpus was chosen to allow an extension to a different dialect of English. The fifth corpus constituted an extension to a totally different recording condition (a rural setting, with large families and many children present, in a typologically different language). The age range also varies a great deal, and it is slightly higher in this last corpus.

Finally, the present study relies on a collaborative annotation effort across several labs. Critically, this means that we can “fairly” compare annotations across our corpora: annotation decisions were either identical or conceptually comparable, and all analyses were

identical. This allows us to more readily answer questions regarding differences in reliability as a function of e.g. child age and language. Also, by looking at corpora that were not annotated in exactly the same way, we can better infer the likelihood with which our results will generalize to other corpora, even if they are not annotated exactly in the same way.

Methods

Corpora. The data for the evaluation comes from five different corpora, annotated in the context of two research projects. The largest one is the ACLEW project (Bergelson et al., 2017; Soderstrom et al., in progress); in this paper we focus on four different corpora of child daylong recordings that have been pooled together, sampled, and annotated in a coordinated manner. These four corpora are: the Bergelson corpus (“BER”) from US English families from the upstate New York area (Bergelson, 2016), the LuCiD Language 0–5 corpus (“L05”) consisting of English-speaking families from Northwest England (C. F. Rowland, Bidgood, Durrant, Peter, & Pine, 2018), the McDivitt and Winnipeg corpora (“MCD”) of Canadian English families (McDivitt & Soderstrom, 2016), and the Warlaumont corpus (“WAR”) of US English from Merced, California (A. Warlaumont, Pretzer, Walle, Mendoza, & Lopez, 2016). Some recordings in BER, and all recordings in MCD and WAR are available from HomeBank repository (VanDam et al., 2016). The second project contains a single corpus collected from Tsimane’ speaking families in Bolivia (“TSI”; C. Scaff, Stieglitz, Casillas, & Cristia, in progress). Socioeconomic status varies both within and across corpora. Key properties of the five corpora are summarized in Table 2.

Despite these differences, all five corpora consists of long (4–16 hour) recordings collected as children wear a LENATM recorder in a LENATM vest throughout a normal day and/or night. For the four ACLEW corpora, out of the 106 recorded participants, daylong recordings from 10 infants from each corpus were chosen for manual annotation, selected to represent a diversity of ages (0–36 months) and socio-economic contexts. In the SOD corpus, sensitive information was found in one of the files, and thus one child needed to be excluded.

Table 2

Key properties of the five corpora

Corpus	Children	Clips	Clip dur (in seconds)	Age mean (range) in months	Location
WAR	10	150	120	6.3 (3-9)	Western US
BER	10	150	120	11.2 (7-17)	Northeast US
SOD	9	150	120	12.3 (2-32)	Western Canada
L05	10	150	120	20 (11-31)	Northwest England
TSI	10	272	60	34 (15-58)	Northern Bolivia

The tenth day for this corpus was a second day by one of the 9 included children. From each daylong file, fifteen 2-minute non-overlapping audio (with a 5-minute context window) were randomly sampled from the entire daylong timeline for manual annotation. This 30-minute sample corresponded to approximately 5-5.6 minutes of annotated speech per daylong file (collapsing across all speaker categories).

The TSI corpus consisted of 1 or 2 recordings from 12 children, out of the 25 children recorded from field work that year; the other 13 had been recorded using other devices (not the LENATM hardware). From these files, 1-minute segments were sampled in a periodic fashion. That is, for each recording, we skipped the first 33 minutes to allow the family to acclimate to the recorder, and then extracted 1 minute (with a 5-minute context window) every 60 minutes, until the end of the recording was reached. This resulted in 4 to 16 minutes of manually annotated audio per child per recording (mean = 12.64 minutes), and an average of 3.4 minutes of speech per key child (collapsing across all speaker categories, and multiple days if present).

We chose to sample 1 or 2 minutes at a time (TSI, and ACLEW corpora, respectively) because conversations are likely to be bursty (Goh & Barabási, 2008). That is, it is likely the case that speech is not produced at a periodic rate (e.g., one phrase every 20 seconds), but

rather it occurs in bursts (a conversation is followed by a long period of silence between the conversational partners, followed by another bout of conversation, perhaps with different interlocutors, followed by silence, and so on). In this context, imagine that you sample a 5-second stretch. If you find speech in that stretch, then it is likely you have by chance fallen on a conversation bout; if you do not find speech, then you have likely found a silence bout. If you were to extend that selection out to several minutes, then it is likely that you will simply add more material from the same type (i.e. conversation bout or silence bout). As a result, any sampling method that favors medium-sized stretches (5-15 minutes) will tend to end up with samples that are internally homogeneous (throughout the 5 minutes, there is a conversation), but highly heterogeneous as a collection if sampling is random throughout the day. This in turn would lead to artificially high correlations between LENATM and human metrics in all dependent variables (e.g., since probably little speech, fewer turns, and fewer child vocalizations will be found in silent bouts and more in conversational ones). Thus, our strategy of sampling randomly/periodically and in short stretches is more likely to capture finer-grained variation in speech quantity.

In the 5 corpora, the 1- or 2-min samples were annotated for all hearable utterance boundaries and talker ID. In ACLEW corpora ¹, talker IDs reflected unique individual talkers, but were coded in such a way to readily allow mapping onto LENATMs talker categories (e.g. key child, other child 1, female adult 1, female adult 2). In the TSI corpus, only the key child and one female adult whose voice recurred throughout the day were individually identified, with all other talkers being classified on the basis of broad age and sex into male adult, female adult, and other children. The ACLEW datasets had other coding levels which will not be discussed here.

Processing. Several different time units are needed to clarify how each metric is calculated (see Figure 1). Clips refer to the 1- or 2-minute samples extracted from recordings.

¹see @casillas2017a and @casillas2017b for the general annotation protocol, and @soderstrom, for an introduction to the databases.

This is the basic unit at which child vocalization counts and conversational turn counts can be established. In addition, since most previous work evaluating adult word counts did so at the clip level, we do so here as well.

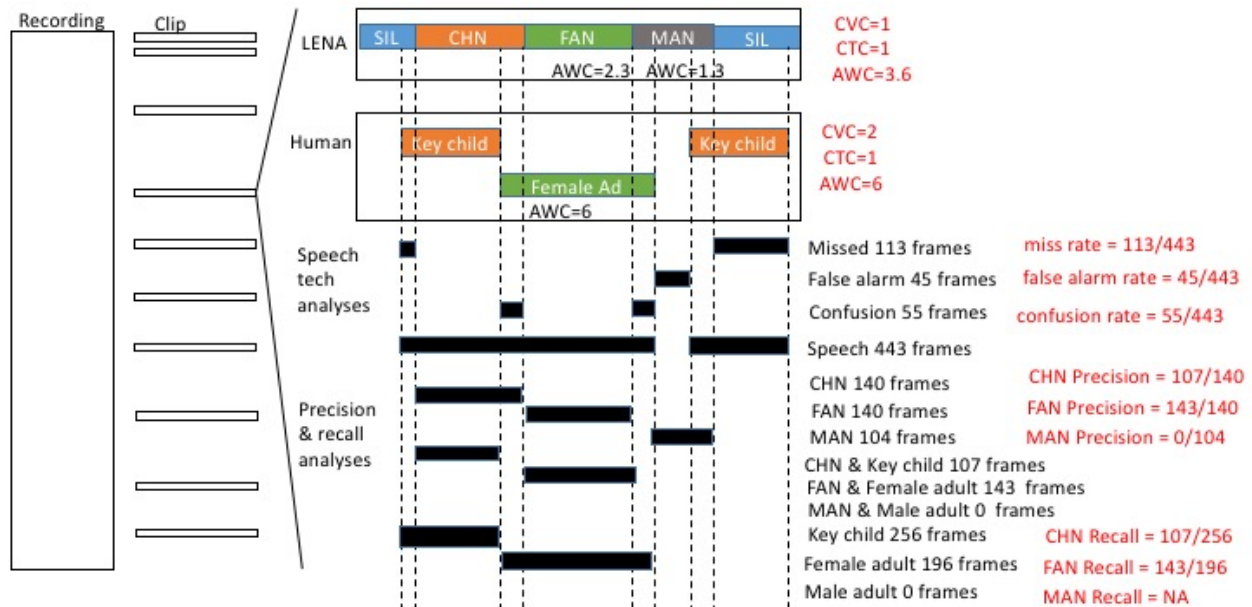

Figure 1. Levels at which performance is evaluated.

The other metrics require a more detailed explanation, conveyed graphically in Figure 1. The stretch of time that has been assigned to a speech or non-speech class by LENATM is a *segment*. In one clip, there may be just one long segment (e.g., the whole clip has been assigned to Silence by LENATM); or there may be more (e.g., the first 5 seconds are attributed to the key child, then there is a 50-second Silence segment, and the final 5 seconds are attributed to a Female Adult). In LENATM's automated analysis, only one of these categories may be active at a given point in time. In contrast, we typically speak of utterances or vocalizations to refer to stretches of speech detected by humans and assigned to different talkers. Again, clips may have zero or more utterances. Unlike LENATM, however, a given point in time may be associated with multiple speakers. Given that there need not be a one-to-one correspondence between LENATM segments and human utterances, we need to define smaller time units that can be used to check for agreement. In this paper,

we use 10 ms frames. This is the basic time unit used for all classification accuracy estimations, which are introduced in more detail in the next subsection.

LENATM classification accuracy. Our first goal was to establish LENATM talker tag accuracy, particularly for the four broad LENATM talker categories (key child, other child, female adult, male adult; or CHN, CXN, FAN, MAN), but taking into account other categories (with some limitation on their interpretation). We calculated accuracy in two complementary ways. First, we used three frame-based standard metrics of speech and talker segmentation to allow direct comparison with other systems in the speech technology literature (False Alarm Rate, Miss Rate, Confusion Rate). We also use Diarization Error Rate, which is derived by summing the first three metrics; together these provide a stringent and standard test of accuracy. Second, we used frame-based precision and recall of each category to provide an intuitive representation of the error patterns shown by this system.

Speech and talker segmentation metrics. The original coding was converted using custom-written python scripts into a standard adaptation of the “Rich Transcription Time Mark” (rttm) format (Ryant et al., 2019), which indicates, for each vocalization or segment, its start time, duration, and speaker. This representation was used in pyannote.metrics (Bredin, 2017) to compute four standard diarization metrics: rate of false alarm for speech, rate of misses for speech, rate of confusion between talkers, and the derived diarization error rate (DER). These are calculated with the following formulas at the level of each clip, where FA (false alarm) is the number of frames during which there is no talk according to the human annotator but during which LENATM found some talk; M (miss) is the number of frames during which there is talk according to the human annotator but during which LENATM found no talk; C (confusion) is the number of frames correctly classified as LENATM as containing talk, but whose voice type has not been correctly identified (when the LENATM model recognizes female adult speech where there is male adult speech for instance), and T is the total number of frames that contain talk according to the human annotation:

Table 3

*Correspondances between LENA and our human annotation. Additional analyses remove one or both of the last two rows. *Electronic voices were only annotated in the ACLEW dataset. Although some Tsimane’ families listen to the radio, radio speech was not annotated in the TSI corpus.*

LENA	Human
CHN	CHI
CXN	OCH
FAN	FA
MAN	MA
TVN*	E*
OLN	OL

- false alarm rate = FA/T ,
- miss rate = M/T ,
- confusion rate = C/T ,
- DER = $(FA+M+C)/T$,

In the human annotation, there is no class representing overlapping speech as such. For the sake of completeness and full comparison with the LENATM model, if two or more different speech sources were active at the same time according to the human annotators, these frames have been mapped to the class “overlap” post hoc. This allows us to compare this Overlap class to LENATM’s OLN (and, for the precision/recall analysis introduced next, OLF) by the LENATM model. Therefore, in the most complete analysis, the confusion rate is computed based on the human-LENATM matches in Table 3.

However, the overlap category is not defined the same way as the LENATM overlap category. For LENATM, overlap between any two categories is labeled OLN – i.e., Noise +

TV would be counted towards overlap as would FAN+FAN; whereas for us, only overlap between two talker categories (e.g., key child and female adult, noise was not coded) counts as overlap. Similarly, the TVN LENATM class is not equivalent to the electronic speech tag in the ACLEW coding, because the former also includes music, singing, crowd noise and any other sound coming from a TV or another electronic source, whereas the latter only includes speech from an electronic source. Therefore, additional analyses map these classes onto “silence” post hoc, so as to not penalize confusions involving them.

Precision and recall. This evaluation looks in more detail at the pattern of errors, by assessing how LENATM and human annotators agreed and disagreed. In both precision and recall, the numerator is the intersection between a LENATM tag and a human tag (e.g., the number of frames that LENATM classified as CHN and the annotator classified as Key child; notice, there is no constraint that these two categories be conceptually the same). The denominator differs: To calculate precision, we divide that number by the total number of frames attributed to a category by LENATM, whereas for recall, we divide by the total number of frames attributed to a category by the human annotator.

CVC and CTC evaluation. From the human annotation, each vocalization by the key child counted towards the total Child Vocalization Count (CVC) for a given clip. For the Conversational Turn Count (CTC), a sequence of key child and any adult (or vice versa) within 5 seconds counted towards the clip total CTC. The Pearson correlation across LENATM and human estimations were calculated.

Users may also wish to interpret the absolute number of vocalizations or turns found by LENATM. Therefore, it is important to also bear in mind absolute error rates, relative error rates, and relative absolute error rates. Despite the similarity in their names, these three metrics provide different information. The absolute error rate tells us, given a LENATM estimate, how close the actual number may be, as it is calculated as $NL - NH$, where NL is the number according to LENATM and NH is the number according to humans. By averaging across clips, we then get an idea of the bias towards overestimation (if this number

is positive) or underestimation (if this difference is negative).

The relative error rate puts this bias in relation to the actual number of vocalizations tagged by the human coder: $(NL-NH)/NL$. For instance, imagine that we find that LENATM errs by 10 vocalizations on average according to the average absolute error rate; this means that, on average across short clips like the ones used here, the numbers by LENATM would be off by 10 vocalizations. We may think this number is small; by using the relative error rate, we can check whether it is small relative to the actual number found: An error of 10 vocalizations would seem less problematic if there are 100 vocalizations on average (LENATM would be just 10% off) than if there are 10 (LENATM would be doubling the number of vocalizations). As with the absolute error rate, the sign of this difference indicates whether LENATM tends to over- or under-estimate these counts.

Finally, the relative absolute error rate is calculated with the formula $\text{abs}(NL-NH)/NL$, where abs indicates that one takes the absolute of the difference. As a result, it cannot be used to assess systematic under- or over-estimation biases, but rather gives an idea of how accurate the estimates are at the clip level (statistically speaking). To convey this intuitively, one could find absolute error rates and relative error rates that are 0 because Otherwise the estimates could be half -100 vocalizations off (for absolute error rates) or -100% off (for the relative error rates), with the other half behaving in the exact opposite fashion.

AWC evaluation. For the AWC portion of this evaluation, we could only use transcriptions from the four ACLEW corpora, since the TSI corpus has not been transcribed (and thus lacks word counts). Annotators for the four ACLEW corpora were proficient in the language spoken in the daylong recording, and transcribed all adult speech based using canonical lexical forms (e.g. “wanna”, not “want to”) in keeping with minCHAT format (MacWhinney, 2017).

Reference adult word counts were determined by counting all unambiguously transcribed words spoken by adult talkers. This was achieved by first discarding all non-lexical transcript entries such as non-linguistic communicative sounds, paralinguistic

markers, and markers indicating incomprehensible speech. In addition, all utterances from the key child and other children were omitted from the Adult Word Count. The remaining orthographic entries separated by whitespaces were then counted as gold standard target words for LENATM to detect. One child in the SOD corpus was learning French. Given our definition of orthographic words with no language-specific processing, we have included this child to increase power, but results without them are nearly identical.

As for LENATM word counts, the regions sampled for manual annotation were not guaranteed to perfectly align with LENATM segments, and human utterances need not align with them either. Of all LENATM segments overlapping with human vocalizations, 14% had only partial overlap with the annotations. To match LENATM AWCs with the annotated word counts, words from the partially overlapping LENATM utterances were included in proportion to the amount of overlap between the LENATM turn and the reference segment in question (e.g., if 10% of a LENATM segment overlapped with a manually-annotated utterance, 10% of the total LENATM AWC estimate for that segment was included in the LENATM word count estimate for that utterance).

AWC were evaluated using Pearson correlations and error rates, similarly to CVC and CTC.

Results

Before starting, we provide some general observations based on the human annotation. Silence is extremely common, constituting 71% of the frames. In fact, 34% of clips contained no speech by any of the speaker types (according to the human annotators). As for speakers, female adults make up 16% of the frames, the child contributes to 6% of the frames, whereas male adult voices, other child voices, and electronic voices are found in only 1% of the frames each. Overlap makes up the remaining 3% of the frames. The following consequences ensue. If frame-based accuracy is sought, a system that classifies every frame as silence would be 71% correct. This is of course not what we want, but it indicates that systems well adapted

to this kind of speech should tend to have low false alarm rates, being very conservative as to when there is speech. If the system does say there is speech, then it had better say that this speech comes from female adults, who provide a great majority of the speech, nearly 3 times as much as the key child and 10 times more than other children or male adults. In fact, given that speech by male adults and other children is so rare, a system that makes a lot of mistakes in these categories may still have a good global performance, because these categories jointly account for only 2% of the frames.

LENATM classification accuracy: False alarms, misses, confusion. Our first analysis is based on standard speech technology metrics, which put errors in the perspective of how much speech there is. That is, if 10 frames are wrong in a file where there are 100 frames with speech, this is a much smaller problem than if 10 frames are wrong in a file where there is 1 frame with speech. In other words, these metrics should be considered relative error metrics. One problem, however, emerges when there is no speech whatsoever in a given file. In the speech technology literature, this is never discussed, because most researchers working on this are basing their analyses on files that have been selected to contain speech (e.g., recorded in a meeting, or during a phone conversation). We still wanted to take into account clips with no speech inside because it is key for our research goals: We need systems that can deal well with long stretches of silence, because we want to measure in an unbiased manner how much speech children hear. Unfortunately, in the 34% of clips that had no speech whatsoever, the false alarm, miss, and confusion rates are all undefined, because the denominator is zero. In all likelihood, this leads to an overestimation of LENATM's performance, because potential false alarms in these files are not counted against the system. It also occurred that there was just a little speech; in this case, the denominator is very small, and therefore the ratio for these two metrics ended up being a very large number. Since means are not robust to outliers, we report on medians.

As mentioned briefly above, there were, a priori, several ways of analyzing the data:

- collapsing near and far together (i.e., CHN and CHF were mapped onto a single CH

category);

- treating the near and far categories separately (i.e., CHN and CHF are both treated as “speakers”, but not the same one);
- not considering TV as a speaker category, since it is conceptually not identical to the electronic voices detected by ACLEW human annotators; in this case, the TV labels are mapped post hoc to “silence”, as are the electronic voices in the human annotation;
- not considering OLN as a speaker category, since it is not conceptually identical to the overlap derived from humans’ annotating different speaker categories; in this case, LENATM’s OL labels are mapped post hoc to “silence”, as are the regions of overlap in the human annotation.

We thought the most informative decision would be to report on several of these settings, albeit briefly. We start with the situation that yields the best LENATM performance: Electronic voices and overlap in the human annotation are mapped onto silence, so that the categories found in the human annotation are FEM, MAL, CHI, OCH; in the LENATM annotation, only CHN, FAN, MAN, and CXN are considered speakers (with all far categories, TVN, and OLN all mapped onto silence). In this setting, LENATM’s false alarm (i.e., saying that a non-silence category is active when none is) had a median of 6%, whereas the miss rate had a median of 33%. The confusion rate, as mentioned above, is only calculated for the correctly detected speech (i.e., not the speech that was missed, which counts towards the miss rate, nor the speech that was falsely identified, which is considered as a false alarm). The confusion rate was very low, with a median of 9%. These three metrics are added together to yield a median diarization error rate over the clips that had some speech of 80%.

In the next best performing case, electronic voices in the human annotation are still mapped onto silence but overlap is not, so that the human categories considered were CHI, FEM, MAL, OCH, and overlap; and the LENATM categories considered were CHN, FAN, MAN, CXN, and OLN (with all far classes and TVN mapped onto silence post hoc). In this

setting, LENATM's false alarm, missed, and confusion rate medians were 32%, 22%, and 27% respectively, for a total median diarization error of 81%. Performance likely degrades because OLN is not picking up the same regions as the overlapping speech found in the human annotations.

Next, we allowed the electronic voices segmented by humans, and TVN among the LENATM speaker categories, to be considered during the evaluation (rather than mapping them all to silence), so that the human categories considered were CHI, FEM, MAL, OCH, overlap, and electronic; and the LENATM categories considered were CHN, FAN, MAN, CXN, OLN, and TVN. LENATM's false alarm, missed, and confusion rate medians were 40%, 19%, and 29% respectively, for a total median diarization error of 88%. Performance likely degrades because TVN is not picking up the electronic speech segmented by ACLEW annotators.

Finally, we declared the maximum possible number of categories: The human categories considered were still CHI, FEM, MAL, OCH, overlap, and electronic; but the LENATM categories considered were CHN, FAN, MAN, CXN, OLN, TVN, CHF, FAF, MAF, CXF, OLF, TVF. LENATM's false alarm, missed, and confusion rate medians were 71%, 7%, and 41% respectively, for a total median diarization error of 119%. Thus, performance degrades considerable when all the “far” classes are treated as speech, leading to huge apparent false alarm rates.

LENATM classification accuracy: Precision and recall. By now, we have established that the best performance (when “far” labels such as CHF and OLF are mapped onto silence, as are TVN and OLN), the overall relative diarization error rate is about 80%, due mainly to missing speech (33%), with false alarms (6%) and confusion between talker categories (9%) constituting a relatively small proportion of errors. These metrics may be insufficient for our readers for two reasons. First, these metrics give more importance to correctly classifying segments as speech versus non-speech (false alarms + misses) than confusing talkers (confusion). Second, many LENATM adopters use the system not to make

decisions on the sections labeled as non-speech, but rather on sections labeled as speech, and particularly those labeled adults and key child. The metrics above do not give more importance to adults and the key child, and they do not give us insight on the patterns of error made by the system.

We therefore turn to precision and recall. Looking at precision of speech categories is crucial for users who interpret LENATM's estimated quantity of adult speech or key child speech, as low precision means that some of what LENATM called e.g. key child was not in fact the key child, and thus it is providing overestimates. Looking at recall may be most interesting for adopters who intend to employ LENATM as a first-pass annotation: the lower the recall, the more is missed by the system and thus cannot be retrieved (because the system labeled it as something else, which will not be inspected given the original filter).

This subsection shows confusion matrices, containing information on precision and recall, for each key category. For this analysis, we collapsed over all human annotations that contained overlap between two speakers into a category called "overlap". Please remember that this category is not defined the same way as the LENATM overlap category. For LENATM, overlap between any two categories falls within overlap – i.e., CHN+TV would be counted towards overlap; whereas for us, only overlap between two talker categories (e.g., key child and female adult) counts as overlap.

We start by explaining how to interpret one cell in Figure 2: Focus on the crossing of the human category FEM and the LENATM category FAN; when LENATM tags a given frame as FAN, this corresponds to a frame tagged as being a female adult by the human 69% of the time. This category, as mentioned above, is the most common speaker category in the audio, so that over 77k frames (representing 69% of the frames tagged as FAN by LENATM) were tagged as being female adult by both the human and LENATM. The remaining 31% of frames that LENATM tagged as FAN were actually other categories according to our human coders: 19% were silence, 8% were in regions of overlap between speakers or between a speaker and an electronic voice, and 4% were due to confusions with other speaker tags.

Figure 2. Precision: Confusion matrix between LENA (x axis) and human annotations (y axis). In each cell, the top number indicates the percentage of all frames in that LENA category (column) that are labeled as a given class by the human (row); cells in a given column add up to 100%. The number below indicates number of frames in that intersection of LENA and human classes.

Inspection of the rest of the confusion matrix shows that, other than silence, this is the most precise LENATM tag.

Precision for CHN comes in second place, at 49%; thus, fewer than half of the frames labeled as being the key child are, in fact, the key child. The majority of the frames, LENATM incorrectly tagged as being the key child are actually silence (or rather, lack of speech) according to the human annotator (25%), with the remaining errors being due to confusion with other categories: About 15% of them are actually a female adult; 2% are another child; and 8% are regions of overlap across speakers, according to our human coders.

MAN and CXN score similarly, 9 and 8% respectively, meaning that less than a tenth of the areas LENATM tagged as being these speakers actually correspond to them. As with the key child, most errors are due to LENATM tagging silent frames as these categories. However, in this case confusion with other speaker tags is far from negligible. In fact, the most common speaker tag in the human annotation among the regions that LENATM tagged as being MAN were actually female adult speech (36%); and, for CXN, it was not uncommon to find a CXN tag for a frame human listeners identified as a female adult (23%) or the key child (8%). In a nutshell, this suggests extreme caution before undertaking any analyses that rely on the precision of MAN and CXN, since most of what is being tagged as such is silence or other speakers.

Another observation is that the “far” tags of the speaker categories do tend to more frequently correspond to what humans tagged as silence (63%) than the “near” tags (41%), and thus it is reasonable to exclude them from consideration. The relatively high proportion of near LENATM tags that correspond to regions that humans labeled as silence could be partially due to the fact that the LENATM system, in order to process a daylong recording quickly, does not make judgments on small frames independently, but rather imposes a minimum duration for all speaker categories, padding with silence in order to achieve it. Thus, any key child utterance that is shorter than .6 secs will contain as much silence as needed to achieve this minimum (and more for the other talker categories). Our system of annotation, whereby human annotators had no access whatsoever to the LENATM tags, puts us in an ideal situation to assess the impact of this design decision, because any annotation that starts from the LENATM segmentation should bias the human annotator to ignore such short interstitial silences to a greater extent than if they have no access to the LENATM tags.

These analyses shed light on the extent to which we can trust the LENATM tags to contain what the name indicates. We now move on to recall, which indicates a complementary perspective: how much of the original annotations attributed to a given class was captured by the corresponding LENATM class.

Figure 3. Recall: Confusion matrix between LENA (x axis) and human annotations (y axis). In each cell, the top number indicates the percentage of all frames that a human labeled as a given class (row) which were recovered in a given LENA category (column); cells in a given row add up to 100%. The number below indicates number of frames in that intersection of LENA and human classes.

Again, we start with an example to facilitate the interpretation of this figure: The best performance for a talker category this time is CHN: Nearly half of the original frames humans tagged as being uttered by the key child were captured by the LENATM under the CHN tag. Among the remaining regions that humans labeled as being the key child, 18% was captured by LENATM's CXN category and 23% by its OLN tag, with the remainder spread out across several categories. This result can be taken to suggest that an analysis pipeline that uses the LENATM system to capture the key child's vocalizations by extracting only CHN regions will get nearly half of the key child's speech. Where additional human

vetting is occurring in the pipeline, such researchers may consider additionally pulling out segments labeled as CXN, since this category actually contains a further 18% of the key child’s speech. Moreover, as we saw above, over a third of these LENATM tags corresponds to the key child, which means that human coders who are re-coding these regions could filter out the two thirds that do not.

Many colleagues also use the LENATM as a first pass to capture female adult speech via their FAN label. Only 28% of the female adult speech can be captured this way. Unlike the case of the key child, missed female speech is classified into many of the other categories, and thus there may not exist an easy solution (i.e., one would have to pull out all examples of many other categories to get at least half of the original female adult). However, if the hope is to capture as much of the female speech as possible, perhaps a solution may be to also pull out OLN regions, since these capture a further 27% of the original female adult speech and, out of the OLN tags, 25% are indeed female adults (meaning that human annotators re-coding these regions need to filter out 4 out of 5 clips, on average).

For the remaining two near speaker labels (MAN, CXN), recall averaged 12%, meaning that less than a quarter of male adult and other child speech is being captured by LENATM. In fact, most of these speakers’ contributions are being tagged by the LENATM as OLN (mean across MAN and CXN 35%) or silence (mean across MAN and CXN 7%), although the remaining sizable proportion of misses is actually distributed across many categories.

Finally, as with precision, the “far” categories show worse performance than the “near” ones. It is always the case that a higher percentage of frames is “captured” by the near rather than the far labels. For instance, out of all frames attributed to the key child by the human annotator, 40% were picked up by the LENATM CHN label versus 0% by the LENATM CHF label. This result can be used to argue why, when sampling LENATM daylong files using the LENATM software, users need not take into account the “Far” categories.

Child Vocalization Counts (CVC) accuracy. Given the inaccuracy of far LENATM tags, and in order to follow the LENATM system procedure, we only counted

vocalizations attributed to CHN and ignored those attributed to CHF. As shown in Figure (CVC), there is a strong association between clip-level counts estimated via the LENATM system and those found in the human annotations: the Pearson correlation between the two was $r = 0.80$ ($p = 0.00$) when all clips were taken into account, and $r = 0.75$ ($p = 0.00$) when only clips with some child speech (i.e., excluding clips with 0 counts in both LENATM and human annotations) were considered. This suggests that the LENATM system captures differences in terms of number of child vocalizations across clips well.

Figure 4. Child Vocalization Counts according to LENA (x axis) and humans (y axis). Each point represents the CVC totaled within a clip. The solid line corresponds to a linear regression fit to data from all clips; the dashed line corresponds to an analysis excluding clips where both the human and LENATM said zero child vocalizations.

The absolute error rate ranged from -47 to 18, with a mean of -2.92 and a median of 0.

Since these numbers can be affected by silent clips, in which both humans and LENATM may trivially agree on there not being any vocalizations, we also calculated the absolute error rate excluding these clips. In this case, the absolute error rate ranged from -47 to 18, with a mean of -5.31 and a median of -4. As for relative error rates, these require the number in the denominator to be non-null. For this analysis, therefore, we need to remove the 379 clips in which the human annotator said there were no child vocalizations whatsoever. When we do this, the mean relative error rate ranged from -100% to 800%, with a mean of -19.66% and a median of -43.75%. Finally, the absolute relative error rate ranged from 0% to 800%, with a mean of 66.84% and a median of 50%. Together, these data suggest that LENA tends to underestimate vocalization counts, particularly when only clips with some speech are considered. This underestimation is quite systematic and it appears to be around half of the actual counts.

Conversational Turn Counts (CTC) accuracy. Again, we only considered “near” speaker categories in the turn count, and applied the same rule the LENATM does, where a turn can be from the key child to an adult or vice versa, and should happen within 5 seconds to be counted. The association between clip-level LENATM and human CTC was weaker than that found for CVC: the Pearson correlation between the two was $r = 0.59$ ($p = 0.00$) when all clips were taken into account, and $r = 0.45$ ($p = 0.00$) when only clips with some child speech (i.e., excluding 381 clips with 0 counts in both LENATM and human annotations) were considered.

The absolute error rate ranged from -75 to 20, with a mean of -9.29 and a median of -3. The absolute error rate excluding clips where both human and LENATM counts were zero ranged from -75 to 20, with a mean of -16.46 and a median of -13. As for relative error rates, these require the number in the denominator to be non-null. For this analysis, therefore, we need to remove the 332 clips in which the human annotator said there were no child-adult or adult-child turns whatsoever. The mean relative error rate ranged from -100% to 400%, with a mean of -67.06% and a median of -83.33%. Finally, the absolute relative error rate ranged

Figure 5. Conversational Turn Counts according to LENA (x axis) and humans (y axis). Each point represents the CTC totaled within a clip. The solid line corresponds to a linear regression fit to data from all clips; the dashed line corresponds to an analysis excluding clips where both the human and LENATM said zero child-adult or adult-child turns

from 0% to 400%, with a mean of 80.31% and a median of 85.71%. For CTCs, as for CVCs, the LENATM seems to be underestimating counts rather systematically, leading to counts that are on average -67.06% smaller than what they actually are.

Adult Word Counts accuracy. The association between clip-level LENATM and human AWC was strong: the Pearson correlation between the two was $r=0.75$ ($p=0.00$) when all clips were taken into account, and $r=0.69$ ($p=0.00$) when only clips with some child speech (i.e., excluding 309 clips with 0 counts in both LENATM and human annotations) were considered. This suggests that the LENATM system captures differences in terms of

number of child vocalizations across clips well.

The absolute error rate ranged from -211 to 157, with a mean of -0.20 and a median of 0. The absolute error rate excluding clips where both human and LENATM counts were zero ranged from -211 to 157, with a mean of 0.46 and a median of -2. As for relative error rates, these require the number in the denominator to be non-null. For this analysis, therefore, we need to remove the 361 clips in which the human annotator said there were no child-adult or adult-child turns whatsoever. The mean relative error rate ranged from -100% to 7400%, with a mean of 55.04% and a median of -17.78%. Finally, the absolute relative error rate ranged from 0% to 7400%, with a mean of 123.89% and a median of 58.33%. Together, these results suggest that LENATM has a strong tendency to underestimate AWC, but there are more random errors in both directions than in the other two counts. We can conclude this from the fact that in the other two counts, the relative error rate and the absolute relative error rate were quite similar, suggesting a stable (underestimation) tendency, whereas here the mean and the median for the relative error rate diverge greatly and both of these are, sign set aside, much smaller than the absolute relative error rate.

Effects of age and differences across corpora. The preceding sections include results that are wholesale, over all corpora. However, we have reason to believe that performance could be higher for the corpora collected in North America (BER, WAR, SOD) than those collected in other English-speaking countries (L05) or non-English speaking populations (TSI). Additionally, our age ranges are wide, and in the case of TSI children, some of the children are older than the oldest children in the LENATM training set. To assess whether accuracy varies as a function of corpora and child age, we fit mixed models as follows.

We predicted false alarm, miss, and confusion rates (when all “F” categories, TV, and overlap were mapped onto silence, which yielded the best results in Section “False alarms, misses, confusion”) from corpus, child age, and the interaction as fixed effects, declaring child ID as random effect, on clips where there was some speech according to the human

annotator. We followed up with an Analysis of Variance (type III) to assess significance. In none of these analyses was corpus, child age, or their interaction significant.

For CVC, we fit a mixed model where CVC according to the human was predicted from CVC according to LENATM, in interaction with corpus and age, as fixed factors, declaring child ID as random effect. An Analysis of Variance (type 3) found a triple interaction, suggesting that the predicted value of LENATM with respect to human CVC depended on both the corpus and the child age; as well as all two-way interactions. To investigate these further, we fit a model where CVC according to the human was predicted from CVC according to LENATM in interaction with age (as fixed factors, with child ID as random) within each corpus separately. This revealed a significant interaction between LENATM CVC and age was only found for BER (indicating that the predictive value of LENATM CVC increased with child age); and that an effect of age was only found for SOD (indicating that CVC went up with age in this corpus). As for the main effect of LENATM CVC, which would be consistent with a predictive value of this metric with respect to human CVC, this emerged as a significant predictor in all corpora but BER.¹

For CTC, we fit a mixed model where CTC according to the human was predicted from CTC according to LENATM, in interaction with corpus and age, as fixed factors, declaring child ID as random effect. An Analysis of Variance (type 3) found no main effects or interactions.

Finally, for AWC, we fit a mixed model where AWC according to the human was predicted from AWC according to LENATM, in interaction with corpus and age, as fixed factors, declaring child ID as random effect. As with CTC, an Analysis of Variance (type 3) found no main effects or interactions.

Discussion

The aim of the present study was to assess LENATM accuracy across key outcome measures: speaker classification accuracy, adult word counts, child vocalization counts, and

conversational turn counts. We did this using a method that avoided inflating accuracy estimates: Saliently, we used random or periodic sampling to select portions of the files for manual annotation, and we did not show our annotators the LENATM segmentation; additionally, our analyses considered both speech and non-speech classes (including electronic sounds and silence). This permitted a systematic, extensive, and independent evaluation of LENATM's key automated metrics. We also tested generalizability by analyzing LENATM's performance across five different corpora: three based on the same population, language, dialect, and age group that LENATM was established for, and trained on (North American English); one that allowed us to test how accurately it captured a different dialect of English (UK English); and one that tested its performance in a totally different recording situation (a rural setting with large families and many children present, speaking a linguistically unrelated language, and where the key children were, on average, somewhat older).

Our first set of analyses tested LENATM's overall accuracy, using established speech and talker segmentation metrics (false alarm rate, miss rate, confusion rate, and the composite diarization error rate), and evaluated the pattern of errors in more detail, by assessing how LENATM and human annotators agreed (precision and recall). The overall diarization error rate was relatively high (79%), mainly due to a high miss rate (missing or excluding speech that was there; 49%). The false alarm rate (identifying non-speech/silence as speech; 12%) and confusion rate (identifying voice type; 10%) were low.

However, this low overall confusion rate (10%) hides considerable errors affecting the interpretation of the output. In terms of precision (to what extent do LENATM tags contain what they say they contain), the system performed relatively well at identifying female voices (52% of frames tagged by LENATM as FAN were coded as female adult by the human coders), and reasonably well at identifying the target child (39% of frames tagged by LENATM as CHN were correct). However, the system performed substantially worse with other talker types (e.g. 8% and 6% for MAN and CXN, respectively); that is, less than a tenth of the frames that LENATM tagged as being speech spoken by these speakers actually

correspond to them.

In terms of recall (how accurately LENATM captured the human annotations), performance for the key child’s vocalizations was relatively robust; almost half of the frames tagged by humans being key child speech were captured by LENATM under the CHN tag. However, recall was poorer for other talkers: only a third of adult female near speech (FAN) and less than 20% of adult male and other child speech were correctly tagged by LENATM.

Our second set of analyses tested the accuracy of three of LENATM’s aggregated counts, namely Child Vocalization Counts (CVC), Conversational Turn Counts (CTC) and Adult Word Counts (AWC). We found high correlations between clip-level counts estimated via the LENATM system and those from the human annotations for AWC and CVC, with weaker performance for CTC. However, such correlational analyses do not establish whether LENATM systematically over- or under-estimates. For this we examined several error rates. While the median absolute error rate for CVC, CTC, and AWC was an encouraging 0%, this was partly due to many clips lacking vocalizations, turns, or adult words altogether. By and large, LENATM systematically underestimates the raw counts of its main quantitative measures - particularly child vocalizations and conversational turns, and to a lesser extent, adult words, which showed more erratic error patterns.

That said, LENATM results were surprisingly robust to dialect, language, and child age, as we found out in our final set of analyses, which tested how well all of these metrics generalized across corpora. We predicted that performance is higher for the corpora collected in North America (BER, WAR, SOD) than those collected in other English-speaking countries (L05) or non-English speaking populations (TSI), and that accuracy decreases with age, since our sample contains children older than those included in the LENATM training set. Contrary to our predictions, there were no significant differences in rates of false alarms, misses, or confusion by corpus, child age or their interaction, nor were there differences between North American and other corpora in terms of CTC or AWC. For CVC, LENATM’s predictions varied across corpora in a way that could not be easily captured by age or dialect.

For instance, LENATM's CVC accuracy increased with age for BER whereas it seemed stable in the other corpora. One caveat is in order for all of these apparently null effects: Absence of a significant difference across corpora and child age may be due to the presence of quite considerable within-corpus variance combined with relatively small human-coded samples from each corpora. Indeed, further work on bigger samples would be needed to ensure sufficient power.

In the meanwhile, we must conclude that there were very few systematic language, dialect, and age effects. This is a promising finding for future speech technology solutions, since it suggests that diarization success may not require large quantities of highly specific training data. This is particularly important for the possibility of using LENATM for languages unrelated to the (dialect of) English for which it was developed. That is, given the significant challenges in creating new datasets for training and testing speech technology, if it indeed turns out to be the case that automated speech processing (e.g. diarization) for daylong recordings is relatively language- or dialect-agnostic in its accuracy, it may be possible to use existing American English corpora with high hopes of generalizability. Please note, however, that since we were unable to compute AWC for Tsimane', we are only able to speak to generalizability across samples and dialects of English for that metric.

In sum, LENATM performs relatively well in terms of overall accuracy, but there are pockets in the system (e.g., identifying male adult voices, establishing absolute numbers of child-adult turns) where the results of the algorithms are quite unreliable. Thus, whether LENATM results are good enough for a given research, educational, or clinical study depends largely on the goals of each particular study. For example, we can describe precision rates of 52% (52% of frames tagged by LENATM as FAN were coded as female adult by human coders) and 39% (39% of frames tagged as target child were also tagged as such by human coders) as being reasonably good. We do this partly because these rates are much higher than LENATM's precision rates for other speakers (all below 10%) but also partly because our frame-based criteria is more stringent than many coding schemes previously applied.

However, that said, whether a particular accuracy rate can be considered good enough, will depend on the purpose of the study. As a result, we next provide a set of recommendations to help researchers make this determination for their goals.

What research goals can one pursue given LENATM's performance? In the present corpora, LENATM's false alarm rate (i.e., identifying speech where there was none) was very low (median of 12%) while its miss rate (missing speech that was actually there) was relatively high (median of 49%). This makes LENATM more suitable for studies in which it is extremely important not to “invent” speech that is not there but less suitable for studies in which capturing most, if not all, of the speech produced is crucial. Based on these findings, LENATM would be a good tool for finding “high talk volume” parts of the day for a) careful further transcription (e.g. of low-frequency events like a certain grammatical construction of interest), b) annotation of specific speech characteristics (e.g. mean length of utterance), or c) comparing relative talk volume across samples. However, we advise caution in using LENATM when raw quantity of speech is crucial for the research question, or when small differences in talk volume might have very significant theoretical consequences; this is often the case in clinical populations where children’s own vocalizations can be an important diagnosis-relevant characteristic (e.g., in children who are deaf or hard of hearing, individuals with ASD, speech apraxia, etc.).

Similarly, although LENATM’s overall confusion rate (i.e. incorrectly identifying talkers, such as giving a ‘mother’ tag for a “child” utterance) was very low (10% of all frames), this does not fully convey the level of accuracy for speech sections, particularly when considering every talker type. In terms of precision, LENATM’s female adult and key child categorization was quite accurate, whereas precision was lower for male adults and other children, such that the vast majority of the frames labeled as male adult or other children did not in fact contain speech by these speaker types. In terms of recall, LENATM was good at capturing speech by the key child as such, but recall was lower for the other voice categories, with again very poor performance for speech by male adults and non-target

children. We, thus, recommend caution before undertaking any analyses that rely on the accuracy (precision and/or recall) of male adult and other children’s speech. For example, if the goal is simply to calculate an overall adult word count (AWC), summing over male and female adult speakers, the fact that there is some confusion between MAN and FAN is likely not problematic. However, if the goal of the study is to compare the relative input from fathers and mothers, LENATM tags are relatively unreliable and on our view, merit further manual vetting in most use cases. As another example, if the goal is to capture as many of the key child’s vocalisations as possible, it might be worthwhile to pull out segments LENATM labelled as non-target child (of which 22% was target child speech) as well, with human coders brought in to filter out non-target child speech.

However, while we recommend LENATM users to be very careful in their use of LENATM diarization and classification, especially for certain talker classes, our results for LENATM count metrics suggest these derived counts may be accurate enough to serve well across a large variety of uses. To begin with, as far as it is possible to generalize from the limited range of samples tested here (children aged 2 to 58 months, learning North American English, UK English, or Tsimane’) it seems that LENATM’s performance does not vary a great deal across ages, dialects, language and home settings. Moreover, correlations between human and LENATM clip-level counts were high to very high, suggesting that the software accurately captures differences in counts across clips (even when error rates were also high). These correlations remained quite high even when clips with counts equal to zero were removed from consideration, suggesting that LENATM captures gradience in vocalization counts.

However, our finding that LENATM generally underestimates the quantity of child vocalizations, child-adult turns, and adult words deserves further consideration. While we feel caution is in order, further work is needed to fully understand the nature and extent of this limitation. Our clips were 1-2 minutes in length, and therefore they either tended to have very little speech or a lot of it. Error rates over hours could be smaller, because local

errors average out; or greater, if the LENATM system systematically underestimates counts. In a LENATM technical report, AWC accuracy was variable across two 12-hour recordings: 1% lower than human transcription for one child, but 27% lower for a second child. This same report notes that AWC accuracy quickly plateaus as recording time increases beyond one hour, leveling to 5-10% in recordings greater than 2 hours in length (D. Xu, Yapanel, & Gray, 2009).

Thus, it is important for further work to help establish the systematicity in LENATM's estimates: if underestimates are robust and systematic (as suggested by present results for CVC and CTC, but not AWC), it may be possible to develop a correction factor to compensate for this bias. However, this bias may be challenging to nail down precisely. For instance, a recent study in Finland documented an overestimate by LENATM, suggested that this raw bias may be context specific (Elo, 2016).

How to test the reliability of LENATM's results. We are overall hopeful that the reliability metrics we provide here will be relevant for researchers working with different populations. We hope the current paper inspires others to evaluate and report all aspects of the system, rather than reporting on a subset of metrics. Similarly extensive evaluations of LENATM in other corpora would bolster the validation literature, and be useful for the whole research community. In fact, it would be useful if researchers systematically test the reliability of LENATM counts in their own samples, especially if they are collecting data from families living in different environments from those assessed here. Next, we provide some guidelines for how to go about this. Note that this requires downloading the audio (.wav) file as well as the LENATM output file.

First, we recommend a literature search, to determine whether a similar sample has been studied in the past for which there exists reliability data (see for example, A. Cristia et al., 2019 for a systematic review). If no studies exist, draw 10 x 2 minutes randomly from 10 children. This is about 3h20min of data, which takes roughly 60h to annotate, in our experience. We recommend training annotators using the ACLEW Annotation Scheme

<https://osf.io/b2jep/>, which has an online test annotators can go through to ensure reliability. Once the annotations are constituted, the LENATM annotations can be extracted and compared against the human annotation using the free DiViMe software (divime.readthedocs.io, Le Franc et al., 2018). This will allow researchers to extract the classification accuracy measures used here (false alarm rate, miss rate, confusion rate and the derived diarization error rate), as well as paired CVC, CTC, and AWC comparing LENATM and human annotations. We note this is only possible if the annotations were made using the ACLEW Annotation Scheme.

Separately, researchers should reflect about the accuracy needed for their question of interest. For instance, suppose we have an evaluation of an intervention where we expect treatment children to hear 20% more speech than controls, or an individual differences study where we expect that the lower fifth of the children hear 20% less speech than the top fifth. If the intended measure used to compare groups has an error rate larger than the effect predicted (such as the the CTC error rate we find here), a different algorithm or outcome metric would be necessary.

Conclusions. In conclusion, in this study, we have provided a broad evaluation of LENATM's accuracy across its key outcome measures (classification, child vocalization counts, conversational turn counts, and adult word counts), and its generalizability across different dialects, languages, ages, and settings. We have provided some recommendations for how to use LENATM in future studies most effectively, and how to test the accuracy of the LENATM algorithms on particular samples of data.

There are, however, a number of areas of research that we have not addressed. For example, we have not investigated how accurately LENATM detects individual variation across children or families. It would be particularly useful to know whether LENATM can classify children with the sensitivity and specificity needed for accurate identification of language disorders. Oller et al. (2010) used LENATM to differentiate vocalizations from 232 typically developing children and children with autism or language delay with a high degree

of accuracy. However, key to this was the use of additional algorithms, not yet available with LENATM, to identify and classify the acoustic features of “speech-related vocal islands” (SVIs). Further work is, thus, needed here.

Even if it turns out that LENATM is not accurate enough to classify children precisely, it may be accurate enough to capture the rank order of individual children’s language growth, which can provide useful information about the relative language level of children in a sample or population (see, e.g., J. Gilkerson et al., 2017). Similarly, LENATM may not capture accurately the precise number of child vocalisations produced over time, but it may track developmental trajectory (e.g., the slope of growth) relatively well. Finally, although our results suggest that aspects of LENATM’s output may be relatively robust to differences across languages and dialects, we need more evidence of how it fares when tracking the language, and language environment, of multilingual children in multilingual homes (see Orena, 2019) for some evidence that LENATM is reliable in French-English bilingual environments although, as in the present paper, it underestimated adult word count]. We look forward to further work that addresses these research questions.

Acknowledgments

This research benefits from the Analyzing Child Language Experiences around the World (ACLEW) collaborative project funded by the Trans-Atlantic Platform for Social Sciences and Humanities “Digging into Data” challenge, including a local Academy of Finland grant (312105) to OR, ANR-16-DATA-0004 ACLEW to AC, NEH HJ-253479-17 to EB, HJ-253479 to CR, and funding from the Social Sciences and Humanities Research Council of Canada to MS. AC acknowledges further support from (ANR-17-CE28-0007 LangAge, ANR-14-CE30-0003 MechELex, ANR-17-EURE-0017); and the J. S. McDonnell Foundation Understanding Human Cognition Scholar Award. MS was also funded by a Social Sciences and Humanities Research Council of Canada Insight Grant (435-2015-0628). EB acknowledges NIH (DP5 OD019812-01). CR was also funded by the Economic and

Social Sciences Research Council (ES/L008955/1). OR was also funded by an Academy of Finland grant no. 314602, MS by a Social Sciences and Humanities Research Council of Canada Insight Grant (435-2015-0628),

Figure 6. Adult Word Counts according to LENA (x axis) and humans (y axis). Each point represents the AWC totaled within a clip. The solid line corresponds to a linear regression fit to data from all clips; the dashed line corresponds to an analysis excluding clips where both the human and LENATM said there were no adult words.

Figure 7. Diarization error rate as a function of corpus and child age (divided into quartiles). Only corpus-quartile combinations with more than 2 children are shown. Central tendency is median. Error bars indicate standard deviation over observations divided by the square root of the number of infants.
